Abstract: This paper presents a comparative study of field oriented control (FOC) and direct power control (DPC) strategies in order to control the active and reactive stator powers of a doubly fed induction generator (DFIG), which is applied to wind energy conversion systems (WECS). Traditionally the FOC is achieved by using of classical Proportional-Integral (PI) controller. However this controller depends highly on parameter variations of the DFIG. The proposed DPC strategy produces a fast and robust power response. Simulation results on a 1.5 MW DFIG system are provided to demonstrate the effectiveness and robustness of the proposed control strategy during variations of active and reactive power, rotor speed, and machine parameters.

Key words: Doubly Fed Induction Generator (DFIG), Field Oriented Control (FOC), Direct Power Control (DPC).

1. Introduction

Since fifteen years, the concept of the variable speed wind turbine (VSWT) equipped with a doubly fed induction generator (DFIG) has received increasing attention due to its noticeable advantages over other wind turbine concepts [1-2]. In the DFIG concept, the stator is usually connected directly to the three-phase grid; the rotor is also connected to the grid but via a transformer and two back-to-back converters (Fig. 1). Usually, the rotor-side converter controls the active and reactive power and the grid side converter controls the DC-link voltage and ensures operation of the converter at a unity power factor [1].

This arrangement provides flexibility of operation in subsynchronous and supersynchronous speeds in both generating and motoring modes (±30% around the synchronous speed). The power inverter needs to handle a fraction (25-30%) of the total power to achieve full control of the generator.

Control of DFIG wind turbine systems is traditionally based on either stator flux oriented control (FOC) [3] or stator voltage oriented control (VOC) [4]. These techniques decouple the rotor current into active and reactive components; control of the active and reactive power is achieved indirectly by controlling the input currents. Some investigations using PI controllers by using FOC that generates reference currents from active and reactive power errors to the inverter or a cascade PI controllers that generate a rotor voltage which has been presented by [5]. Therefore, the conventional PI controllers, because of their simple structures, are still the most commonly used control techniques in power systems, as can be seen in the control of the wind turbines equipped with DFIGs [4-5-6-7]. Unfortunately, tuning the PI controllers is tedious and it might be difficult to tune the PI gains properly due to the nonlinearity and the high complexity of the system. Another main drawback of this regulator is that its performance depends greatly on accurate machine parameters pertaining to the resistances (by warming-up) and inductances (by saturation).

In the last fifteen years, a new technique, based on the Direct Torque Control (DTC) introduced by I. Takahashi in 1986 [8], the Direct Power Control (DPC), was developed and presented in 1998 by T. Noguchi [9] and applied to DFIG in 2006 by L. Xu [10]. DPC is characterized by its fast dynamic response, simple structure and robust response against parameter variations and it does not utilize a rotor current control loops. In the DPC strategy, the active and reactive powers are estimated, using current measurements, and controlled directly with hysteresis controllers and a switching table similar to the one used in DTC applied for AC machines [10-11]. At last, the main characteristics, advantages and disadvantages of both methods are shown and discussed in the results of the simulation tests of a 1.5MW DFIG by using MATLAB/SIMULINK software.

2. Wind turbine model

Fig. 1. WECS based a DFIG configuration.
The relation between the wind speed and mechanical power, delivered by the wind turbine, can be described by the following equation:

\[ P_t = \frac{1}{2} \rho \pi R^2 v^3 C_p(\lambda, \beta) \]  

where:

\[ C_p: \text{power coefficient}; \lambda: \text{relative speed}; \beta: \text{pitch angle (deg)}; R: \text{radius of turbine (35.25 m)}; \Omega: \text{turbine speed (rd/s)}; \rho: \text{air density (1.225 kg.m}^{-3}), \varepsilon). \]

For the VSWT, the approximate expression of the power coefficient can be described by the following expression [12]:

\[ C_p = f(\lambda, \beta) = C_1 \left[ C_2 - C_3 \beta - C_4 \right] \exp \left( \frac{-C_5}{\lambda} \right) + C_6 \lambda \]  

where:

\[ C_1 = 0.5176; \quad C_2 = 116; \quad C_3 = 0.4; \quad C_4 = 21; \quad C_5 = 0.0068. \]

\[ \frac{1}{\lambda} = \frac{1}{\lambda + 0.08 \beta} + 1 \]  

The electromagnetic torque produced by the turbine is expressed in the following way:

\[ T_t = \frac{P_t}{\Omega_r} = \frac{1}{2} \rho \pi R^2 v^3 C_1(\lambda, \beta) \]  

where \( C_1 \) is the torque coefficient expressed by:

\[ C_1 = \frac{C_p}{\lambda} \]  

Fig. 2 shows the characteristic of the torque coefficient, with a fixed pitch angle \( \beta \), for the 1.5MW turbine used in this work.

3. Modeling of the DFIG

In the synchronous \( d-q \) reference frame rotating at \( \omega_r \) speed, the model of the DFIG is given by the following equations:

Stator voltage components:

\[ \begin{align*}
    V_{ds} &= R_s I_{ds} + \frac{d}{dt} (\psi_{ds} - \omega \psi_{qs}) \\
    V_{qs} &= R_s I_{qs} + \frac{d}{dt} (\psi_{qs} + \omega \psi_{ds})
\end{align*} \]  

Rotor components:

\[ \begin{align*}
    V_{dr} &= R_s I_{dr} + \frac{d}{dt} (\psi_{dr} - (\omega_r - \omega) \psi_{qr}) \\
    V_{qr} &= R_s I_{qr} + \frac{d}{dt} (\psi_{qr} + (\omega_r - \omega) \psi_{dr})
\end{align*} \]  

Stator flux components:

\[ \begin{align*}
    \psi_{ds} &= L_s I_{ds} + L_m I_{dr} \\
    \psi_{qs} &= L_s I_{qs} + L_m I_{qr}
\end{align*} \]  

Rotor flux components:

\[ \begin{align*}
    \psi_{dr} &= L_s I_{dr} + L_m I_{ds} \\
    \psi_{qr} &= L_s I_{qr} + L_m I_{qs}
\end{align*} \]  

DFIG electromagnetic torque:

\[ T_{em} = -\frac{3}{2} p \frac{L_m}{L_s} (\psi_{ds} I_{qr} - \psi_{qr} I_{ds}) \]  

Mechanical equation:

\[ T_r = T_{em} + J \frac{d\Omega}{dt} + f \Omega, \]  

Generator active and reactive powers at the stator side are given by the expressions:

\[ \begin{align*}
    P_s &= \frac{3}{2} (V_{ds} I_{ds} + V_{qs} I_{qs}) \\
    Q_s &= \frac{3}{2} (V_{ds} I_{ds} - V_{qs} I_{qs})
\end{align*} \]  

3. Field oriented control strategy

The rotor-side converter is controlled in a synchronously rotating \( d-q \) axis frame, with the \( d \)-axis oriented along the stator flux vector position (Fig. 3). In this approach, decoupled control between the stator active and reactive powers is obtained. The influence of the stator resistance can be neglected and the stator flux can be held constant as the stator is connected to the grid. Consequently [9]:

\[ \psi_{ds} = \psi_s \quad \text{and} \quad \psi_{qs} = 0 \]
Since the stator is directly connected to the grid and the stator flux can be considered constant, and if the voltage dropped in the stator resistance has been neglected [5-6], the voltage equations, flux equations, currents equations and stator active and reactive powers equations can be simplified in study state as:

\[
\begin{align*}
V_{ds} &= 0 \\
V_{qr} &= V_s = \omega_s \psi_s \\
\psi_s &= L_s I_{ds} + L_m I_{dr} \\
0 &= L_s I_{qs} + L_m I_{qr} \\
I_{ds} &= \frac{\psi_s}{L_s} - \frac{L_m}{L_r} I_{dr} \\
I_{qr} &= -\frac{L_m}{L_s} I_{qr} \\
P_s &= \frac{3}{2} V_s I_{ds} \\
Q_s &= \frac{3}{2} V_s I_{ds}
\end{align*}
\]

Replacing the stator currents by their expressions given in (17), the equations below are expressed:

\[
\begin{align*}
P_s &= -\frac{3}{2} \frac{L_m}{L_s} V_s I_{qr} \\
Q_s &= \frac{3}{2} V_s \left( \frac{V_s}{L_s \omega_s} - \frac{L_m}{L_s} I_{ds} \right)
\end{align*}
\]

The electromagnetic torque is as follows

\[
T_m = -\frac{3}{2} \frac{L_m}{L_s} \psi_s I_{qr}
\]

Due to the constant stator voltage, the stator active and reactive powers are controlled by means of \( I_{qr} \) and \( I_{ds} \) respectively. We could express the rotor voltages according to the rotor currents, thus we obtain:

\[
\begin{align*}
V_{dr} &= R_s I_{dr} - g \omega_s \left( L_s - \frac{L_m^2}{L_r} \right) I_{qr} \\
V_{qr} &= R_s I_{qr} + g \omega_s \left( L_s - \frac{L_m^2}{L_r} \right) I_{dr} + g \frac{L_s V_s}{L_r}
\end{align*}
\]

The pole-placement method is used to design PI controllers in current control loops and power control loops [5-6]. Consequently, the resulting overall control system implemented on the DFIG corresponds to the block diagram presented in Fig. 4.

4. Direct power control strategy

The DPC is based on the same control principles as the DTC technique, the unique difference is the directly controlled variables. In the case of the DTC, the electromagnetic torque and the rotor flux are directly controlled while in the DPC, the stator active and reactive powers are controlled. First a conceptual study of the classical DPC technique will be carried out. In this section, we present the direct control of active and reactive powers by using tow levels voltage source inverter (2L-VSI) which supplies the rotor windings as we show in Fig. 5.

A. Stator active and reactive power estimation

Instead of measuring the two powers on the line, we capture the rotor currents, and estimate \( P_s \) and \( Q_s \). This approach gives an anticipated control of the powers in the stator windings. By using the stator flux oriented
control and previous equations presented in section 3
with hypothesis of \((R_s = 0)\), we can find the relations of 
the stator active and reactive powers \(P_s\) and \(Q_s\) 
to both components of the rotor flux in the stationary 
\(\alpha, \beta\) reference frame, and we can get:

\[
\begin{align*}
P_s &= -\frac{3}{2} \frac{L_m}{\alpha_s L_r} \psi_{\alpha s} \\
Q_s &= -\frac{3}{2} V_s \left( \frac{1}{\alpha_s} \psi_{s} - \frac{L_m}{\alpha_s L_r} \psi_{s r} \right)
\end{align*}
\]

(22)

Where:

\[
\begin{align*}
\psi_{s \alpha} &= \left( L_r - \frac{L_m^2}{L_r} \right) \psi_{s \alpha} + \frac{L_m}{L_r} \psi_{s \beta} \\
\psi_{s \beta} &= \left( L_r - \frac{L_m^2}{L_r} \right) \psi_{s \beta} \\
\psi_{s} &= \sqrt{\psi_{s \alpha}^2 + \psi_{s \beta}^2} \\
\psi_{s \sigma} &= \left| \frac{\psi_{s \beta}}{\psi_{s \alpha}} \right| \omega_s \\
\sigma &= 1 - \frac{L_m}{L_r}
\end{align*}
\]

(23)

If we introducing the flux power angle \(\delta\) between stator 
and rotor flux space vectors, \(P_s\) and \(Q_s\), become:

\[
\begin{align*}
P_s &= -\frac{3}{2} \omega_s |\psi_s| |\psi_{s \sigma}| \sin \delta \\
Q_s &= -\frac{3}{2} \omega_s |\psi_s| |\psi_{s \sigma}| \cos \delta - |\psi_{s \sigma}| 
\end{align*}
\]

(24)

Differentiating (24) results in the following equations:

\[
\begin{align*}
\frac{dP_s}{dt} &= \frac{3}{2} \omega_s |\psi_s| |\psi_{s \sigma}| \frac{d|\psi_{s \sigma}| \sin \delta}{dt} \\
\frac{dQ_s}{dt} &= \frac{3}{2} \omega_s |\psi_s| |\psi_{s \sigma}| \frac{d|\psi_{s \sigma}| \cos \delta}{dt}
\end{align*}
\]

(25)

As we see in (25), these last two expressions show that the stator active and reactive powers can be 
controlled by modifying the relative angle between the 
rotor and stator flux space vectors and their amplitudes. 
This effect is illustrated in the next sections.

**B. Switching table**

The references of active and reactive powers values 
are compared with the estimated ones respectively in 
hysteresis controllers, with \(S_p\) and \(S_q\) are the outputs 
signal of active and reactive powers controllers respectively.

We elaborated the switching table of the control 
structure; according to the outputs of the controllers \(S_p\), 
\(S_q\) and the rotor flux position \(\delta\).

For this purpose, the evolution space of \(\psi_r\) in the 
considered reference frame is divided into six sectors; 
this choice is dictated by preoccupation with a more 
rigorous control, and such as:

\[
-\frac{\pi}{6} + (k - 1)\frac{\pi}{3} \leq \delta(k) \leq \frac{\pi}{6} + (k - 1)\frac{\pi}{3}
\]

(26)

With: \(k = 1, 2 \ldots 6\)

The digitized error signal \(S_p\), \(S_q\) and the rotor 
flux sector are input to the switching table in which 
every switching state \(S_p, S_q\) and \(S_r\) of the 2L-VSI is 
stored as shown in Table 1.

**C. Rotor active voltage vectors effect on powers**

Considering that the stator flux space vector amplitude 
is constant, the stator active and reactive powers only 
depend on the relative angle between the fluxes \(\delta\), 
and the rotor flux space vector amplitude. 
Considering anticlockwise direction of rotation of the 
flux vectors in the rotor reference frame to be positive, 
it may be noted that \(\psi_r\) is ahead \(\psi_s\) in rotor active voltage 
vector.

![Fig. 6. Flux vectors in rotor coordinates for generating mode.](image-url)
Assuming that the rotor flux is located in the first sector, the application of voltages vectors \( V_2 \) and \( V_3 \) results in a decrease in the stator active power whereas, the application of vectors \( V_3 \) and \( V_6 \) would increase it. In the other hand, the application of \( V_2 \) and \( V_6 \) would decrease the reactive power drawn from the stator side, while \( V_1 \) and \( V_3 \) would increase it.

As a generalization it can therefore, be said that if the rotor flux resides in the \( k^{th} \) sector, where \( k = 1, 2, \ldots, 6 \), the application of voltage vectors \( V_{k+1} \) and \( V_{k+2} \) would decrease the delivered stator active power, while the vectors \( V_{k-1} \) and \( V_{k+2} \) would increase it. Moreover, the application of \( V_{k+1} \) and \( V_{k+2} \) would decrease (-) the delivered reactive powers, while \( V_{k-1} \) and \( V_{k+2} \) would increase (+) it, while the zero voltage vectors have a neglected (0) effect in \( Q \). Then, for each sector, only four active vectors are permitted \((V_{k-2}, V_{k+1}, V_{k-1}, V_{k+2})\) and the zero vectors \((0,0)\).

The expected direction of change in \( Q_s \) due to the application of any switching state in the different sectors can be summarized in Table 2.

### Table 2

</tbody>
</table>

In case of discrepancy, the current sector must be updated according to Table 3 [13], by shifting its position clockwise (-1), antriclockwise (+1), or just keeping its previous position (0). The DPC sampling period must be small enough so as to never miss the shift of the rotor flux between two adjacent sectors. It may however, be noted that in a particular sector not all vectors will be applied. For example, in the \( k^{th} \) sector, vectors \( V_k \) and \( V_{k+2} \) will never be applied [14].

**D. Zero voltage vector effect on powers**

Notice that the order of voltage vectors is opposite in subsynchronous operation with respect to supersynchronous operation. The zero voltage vectors \( V_6 \) and \( V_9 \) stall the rotor flux vector without affecting its magnitude. Their effect on active power is thus opposite in subsynchronous and supersynchronous operation.

In subsynchronous motoring, application of a zero vector increases \( \psi_r \) keeps rotating in the positive direction at slip speed. Above the synchronous speed, \( \psi_r \) rotates in the anticlockwise direction thereby reducing \( \delta \); hence active power drawn by the stator increases for subsynchronous operation and decreases for supersynchronous operation. Active power generated being negative, the same conclusion holds true for the generating modes as well.

Since a zero vector does not change the magnitude of the rotor flux its effect on the reactive power is rather small. Nevertheless, there is some small change in \( Q_s \); its effect being dependent on whether the angle between the stator and rotor fluxes increases or decreases due to the application of a zero vector. An increase (↑) in angular separation between the two fluxes reduces (↓) \( \psi_s \) resulting in an increment (↑) of \( Q_s \) drawn from the stator side. The converse is true when \( \delta \) reduces. It is observed that the change in \( Q_s \) due to the application of the zero vectors is different in all the 4 modes of operation. This is summarized in Table 4.

### 5. Simulation results

In this part, simulations are investigated with a 1.5MW DFIG connected to a 398V/50Hz grid (appendix), by using the MATLAB/SIMULINK software in fixed-step size of 0.1ms. The both control strategies FOC and DPC are simulated, tested and compared in terms of power reference tracking, robustness against machine parameter variations and stator current harmonics distortion.

1) Power reference tracking: in this test, we initial simulation with various active and reactive powers steps in nominal regime of DFIG with a normal rotor operating speed range (1000 rpm to 2000 rpm) and nominal stator voltage). The active power step is changed from -0.5MW to -1.5MW at the instants \( t = 0.35s \) and again from -1MW to -0.5MW at the instant \( t = 0.7s \); while the reactive power step is changed from -0.5MVAR to 0.5MVAR at the instant \( t = 0.45s \). (The negative sign ‘-’ refers to the generation of active power and to the absorption of reactive power). The simulation results are show in Fig. 7 for the FOC strategy and in Fig. 8 for the DPC strategy.
Fig. 7. FOC strategy responses.

Fig. 8. DPC strategy responses.
The results steps responses in Fig. 7 and Fig. 8 show that the decoupled control of active and reactive power is achieved for both strategies, the two controllers pursue the references powers, but the DPC strategy show a faster time response (2.13ms for active power and 1.97ms for reactive power) than the FOC strategy (0.09s for active power and 0.08s for reactive power).

2) DFIG parameter variations: to test the impact of parameters variations on the performances of each strategy, we increase the rotor resistance ($R_r$) of 100% (case of warming-up of rotor windings) and decrease the mutual inductance ($L_m$) of 10% (case of inductances saturation). Fig. 9 shows the simulation results.

Simulation results on Fig. 9-(b) shows the robustness of the DPC strategy against parameter variations of the DFIG especially to the mutual inductance variations; this does not depend on the machine parameters contrary to the FOC strategy [Fig. 9-(a)] that more heavily depends on machine parameters.

3) Current harmonics distortion: in the last test, the reactive power reference will be set to zero ($Q_s^* = 0$ MVAR) to ensure a unity power factor (PF) at the grid side, in order to optimize the generated stator active power quality. In this case the THD rate of the stator current in each strategy can be evaluated by using the Fast Fourier Transform (FFT); the THD is evaluated for two cycles. The results are presented in Fig. 10.

![Fig. 9. Both control strategies responses against parameter variations of DFIG: (a) for FOC strategy and (b) for DPC strategy.](image)

![Fig. 10. THD rate, (a) for FOC strategy, (b) for DPC strategy.](image)
On the other hand, unitary power factor at the grid side of DFIG is kept during the transition of the stator current both in FOC strategy [Fig. 10-(a)] and DPC strategy [Fig. 10-(b)]; while \( Q_s = 0 \) and \( P_s \) is varied.

The current harmonic distortion test of the two strategies presented in Fig. 10 shows that the harmonics rate in the case of the DPC strategy [Fig. 10-(b)] is more significant (5.95\%) than those in the case of the FOC strategy, which is only 5.17\% [Fig. 10-(a)], and it’s due to the use of hysteresis controllers and the switching table in the first one witch result in the variable switching frequency.

Finally, the Table 5 summarizes the principal differences between the FOC strategy and the DPC strategy.

### 6. Conclusions
This paper has presented a comparative study between two control strategies of active and reactive powers for Doubly Fed Induction Generator, the: FOC and DPC. The first one is based on PI controllers and the second one on hysteresis controllers and a switching table. So as to evaluate the performances of each strategy, we have put the two strategies under various conditions such as: changing powers steps references, and parameters variations of the DFIG.

The comparisons of simulation results between tow strategies show that for both strategies the decoupled of active and reactive power is achieved. But, in steady state of DFIG, the DPC strategy presents a high dynamic response, and it’s more robust against parameters variation of the DFIG.

However this strategy because of the variable switching frequency presents the drawback to having a high frequency of switching which present a high harmonic distortion of the generated currents, high ripples of active and reactive powers, and warming-up of the silicon switchers compared to the FOC strategy.

Then, the big criterion to engineers and researches is to choose between both strategies mainly the requirements of the application in terms of high performances in ideal conditions and robustness in the case of parameters variations, involved in the field of DFIG based wind energy conversion systems.
